

# THE RADIO SKY AT METER WAVELENGTHS: *M*-MODE ANALYSIS IMAGING WITH THE OWENS VALLEY LONG WAVELENGTH ARRAY

MICHAEL W. EASTWOOD, GREGG HALLINAN

## ABSTRACT

I present all-sky maps of the sky from the Owens Valley Long Wavelength Array. These maps are created from the application of *m*-mode analysis.

## 1. INTRODUCTION

Studies of the cosmic microwave background (CMB) have given us an unprecedented understanding of the universe during the epoch of recombination (Hinshaw et al. 2013). Following the epoch of recombination the universe continued to expand and cool. Small inhomogeneities observed in the CMB grew larger and galaxies formed. The first stars formed and flooded the universe with light during the cosmic dawn, bringing the dark ages to an end. Eventually the cumulative influence of these galaxies completed a phase change in the intergalactic medium (IGM), and the universe returned to an ionized state following the conclusion of the epoch of reionization (EoR). Low frequency radio telescopes are poised to provide the first direct detection of the IGM from the cosmic dawn and the EoR using the redshifted hyperfine structure line of neutral hydrogen.

These low-frequency 21-cm cosmology experiments are limited by the dynamic range they can achieve against the low-redshift sources of emission. Depending on the redshift, length scale, and model the expected amplitude of the cosmological signal is 10 to 100 mK. On the other hand the galactic synchrotron emission is 1000 to 10000 K. **TODO: citation** Therefore experiments conservatively need to achieve at least 4 orders of dynamic range. In theory this kind of dynamic range can be obtained by exploiting the fact that the foreground emission is predominantly synchrotron emission that has a smooth power law spectrum. On the other hand the frequency structure of the cosmological signal is expected to be un-smooth because different frequencies trace different redshifts. This is the basic assumption made by all published upper limits on the cosmological 21 cm power spectrum. In practice the interferometer itself imparts frequency structure into the measurements and therefore an experiment’s ability to separate the foreground signal from the cosmological signal can be limited by the instrumental spectral smoothness.

Ideally the foreground removal strategy should be informed by the measured spatial and frequency structure

of all foreground components. This possibility is limited by the availability of suitable high-fidelity low-frequency sky maps on angular scales ranging from tens of degrees to arcminutes.

The Global Sky Model (GSM) (de Oliveira-Costa et al. 2008; Zheng et al. 2017a) is a data-driven interpolation of various maps between 10 MHz and 100 GHz. However the majority of information contained in the GSM is derived at higher frequencies where the majority of the input maps are from. Below 408 MHz, the interpolation is largely driven by the Haslam 408 MHz map (Haslam et al. 1981, 1982). At lower frequencies, free-free absorption and synchrotron self-absorption becomes increasingly important and hence spectral indices derived at higher frequencies need corrections at lower frequencies.

## 2. OBSERVATIONS

### 2.1. The Owens Valley Long Wavelength Array

The Owens Valley Long Wavelength Array (OVRO LWA) is a 288-element interferometer located at the Owens Valley Radio Observatory (OVRO) near Big Pine, California. The OVRO LWA is a low-frequency instrument with instantaneous bandwidth covering 24.768 MHz to 82.296 MHz **TODO: double check this frequency range, I think it’s wrong**. Each antenna stand hosts two perpendicular broadband dipoles so that there are  $288 \times 2$  signal paths in total. These signal paths feed into the 512-input LEDA correlator, which allows the OVRO LWA to capture the entire visible hemisphere in a single snapshot image. In the current configuration, 32 antennas (64 signal paths) are unused.

The 288 antennas are arranged in a maximally non-redundant configuration optimized for minimum side-lobes in snapshot imaging. 251 of these antennas are contained within a 200 m diameter core that is inde-

**Figure 1.** This figure shows the antenna layout for the OVRO LWA. The 200 meter diameter area indicated by the dashed line contains 251 antennas distributed in a pseudo-random configuration. The 32 filled circles are the expansion antennas built in early 2016 to increase the longest baseline to 1.5 km. The 5 open circles are antennas equipped with noise-switched front ends.

pendently optimized for imaging sidelobe levels. 32 antennas are placed outside of the core in order to extend the maximum baseline length out to  $\sim 1.5$  km. The final 5 antennas are equipped with noise-switched front ends for calibrated total power measurements of the global sky brightness. These antennas are used as part of the LEDA experiment to measure the global signal of 21 cm absorption from the cosmic dawn. **TODO: cite a leda paper** Calibrated total power measurements from these antennas will be used to constrain sky modes with  $l \lesssim 2$  including the monopole. **TODO: What values of  $l$  actually contribute to the total power measurements?**

## 2.2. The OVRO LWA 100 Hour Dataset

Because the correlator only accepts 512 inputs (256 antennas with 2 polarizations for each antenna), a subset of the antennas must be selected for correlation.

Include plot of antenna layout.

The integration time is 13 seconds. This was chosen because the remainder of one sidereal day divided into 13 second intervals is only 90 milliseconds. Finer control of the integration time is not possible due to technical constraints.

## 2.3. Antenna Gain Calibration

Antenna gain calibration is accomplished using an iterative method independently developed by Mitchell et al. (2008) and Salvini & Wijnholds (2014). The calibration routine is written in the Julia programming lan-

guage (Bezanson et al. 2017), and is publicly available online<sup>1</sup> under an open source license (GPLv3+).

The antenna complex gains are updated once per day from a 9 hour track of data when Cas A and Cyg A are at high elevations. These two sources are – by an order of magnitude – the brightest radio sources in the northern hemisphere. Therefore the optimal time to solve for the interferometer’s gain calibration is when Cas A and Cyg A are at high elevations. A calibration obtained in this manner is good consistent with the following day’s calibration to within a 1% error in the flux scale and 1’ error in the astrometry **TODO: double check these numbers**. These residual errors are likely driven by differing ionospheric conditions.

The flux scale is tied to the work of Perley & Butler (2016).

Temperature fluctuations within the electronics shelter generate 0.1 dB sawtooth oscillations in the analog gain. These oscillations occur with a variable 15 to 17 minute period. The amplitude of these gain fluctuations is calibrated by smoothing the autocorrelation amplitudes on 45 minute timescales. The ratio of the measured auto-correlation power to the smoothed auto-correlation power defines a per-antenna amplitude correction that is then applied to the cross-correlations.

## 2.4. Source Removal

### 2.4.1. Cassiopeia A and Cygnus A

Without removing bright sources from the data, sidelobes from bright sources will dominate the variance in the image. At 74 MHz Cyg A is a 15,000 Jy source (Perley & Butler 2016). A conservative estimate for the confusion limit at 74 MHz with a 10 arcminute beam is 500 mJy (Lane et al. 2012). Therefore we require that Cyg A’s sidelobes be at most of  $-45$  dB down from its peak flux to prevent Cyg A’s sidelobes from dominating the variance in the image. **TODO: Measure Cyg A’s sidelobe levels if it is not subtracted**

At low frequencies, propagation effects through the ionosphere must be accounted for in order to achieve high dynamic range images. This necessitates the use of direction-dependent calibration and peeling (Mitchell et al. 2008; Smirnov & Tasse 2015). In the dataset used in this paper, scintillation and diffraction events on the timescale of a single integration (13 seconds) are observed. Therefore the direction dependent calibration changes on these timescales and the we must solve for one set of complex gains per source per integration.

The largest angular scale of Cas A is  $\sim 8$  arcminutes, while the largest angular scale of Cyg A is  $\sim 2$  arcminutes. With a 10 arcminute resolution, the OVRO LWA

<sup>1</sup> <https://github.com/mwestwood/TTCal.jl>

marginally resolves both sources. A resolved source model is needed for both sources. We fit a self-consistent resolved source model to each source. This is performed by minimizing the variance within an aperture located on each source after peeling. By phasing up a large number of integrations before imaging (at least over 1 hour) it is possible to smear out the contribution of the rest of the sky. We then use NLOpt's Sbplx routine (Johnson 2008; Rowan 1990) to vary the parameters in a source model until the variance within the aperture is minimized.

**TODO: Show a before and after with the updated source models**

**TODO: Give a plot with the updated source models**

#### 2.4.2. The Sun

The Sun can be trivially removed from any map of the sky by constructing the map using only data taken at night. A map of the entire sky can be obtained by using observations spaced 6 months apart. However the OVRO LWA 100 hour dataset consists of 100 consecutive hours of data, and hence roughly half of the data is from the day.

The Sun is a time variable source in radio.

**TODO: does the previous routine work on the Sun too? worth a shot**

#### 2.4.3. Sparking Power Lines

The Owens Valley is an important source of water and power for the city of Los Angeles. Unfortunately this means that high voltage power lines run along the valley to the west of the OVRO LWA. Some of these power line poles have faulty insulators that arc and produce pulsed, broadband RFI. Because these poles exist in the near-field of the array, we have been able to localize some of them by using the curvature of the incoming wavefront. Efforts are currently underway to work with the utility pole owners to have these insulators replaced.

In the meantime it is possible to suppress their contamination in the dataset. The contribution of these RFI sources to the visibilities can be plainly seen by averaging >24 hours of data with the phase center set to zenith. In this way, true sky components are smeared along tracks of constant declination while terrestrial sources (ie. the arcing power lines) are not smeared. For similar reasons, when constructing a map of the sky from >24 hours of data these sparking power lines will produce artifacts in the map that are smeared along tracks of constant declination. However while the amplitude of the RFI will fluctuate with time, its phase will be constant. Therefore if you can use isolate a set of model visibilities for the RFI, it can be removed from each integration by scaling and subtracting these model visibilities from the measured visibilities.

Obtaining a model for the RFI is complicated by the fact that the contaminating sources are at extremely low elevations where the antenna response is maximally inhomogeneous. Therefore it is not enough to know the physical location of the faulty insulator generating the RFI. In addition you must also know the response of each antenna (amplitude and phase) in the appropriate direction. This motivates the use of peeling, which allows the antenna response to be a free parameter.

Therefore model visibilities for the RFI can be obtained by peeling the sources after smearing the visibilities over >24 hours. These model visibilities are then scaled and subtracted from each integration in the data set.

**TODO: show an example smeared image before and after peeling**

#### 2.5. Fitting the Antenna Response

In order to generate wide-field images of the sky, the response of the antenna to the sky must be known. Fortunately drift-scanning interferometers like the OVRO LWA can empirically measure their primary beam under a mild set of symmetry assumptions (Poher et al. 2012). In this work we assume that the primary beam is invariant under north-south and east-west flips, and additionally that the  $x$ - and  $y$ -dipoles have the same response to the sky after rotating one by  $90^\circ$ . We measure the flux of several point sources **TODO: which ones??** as they pass through the sky and then fit a beam model composed of Zernike polynomials to those flux measurements. We select the basis functions to have the desired symmetry.

### 3. IMAGING

The goal of all imaging algorithms is to estimate the brightness of the sky  $I_\nu(\hat{r})$  in the direction  $\hat{r}$  and frequency  $\nu$ . A radio interferometer measures the visibilities  $V_{ij,\nu}$  between pairs of antennas – here numbered  $i$  and  $j$  respectively. If the antennas are separated by the baseline  $\vec{b}_{ij}$ , and  $A_\nu(\hat{r})$  describes their response to the incident radiation, then

$$V_{ij}^{ij} = \int_{\text{sky}} A_\nu(\hat{r}) I_\nu(\hat{r}) \exp\left(2\pi i \hat{r} \cdot \vec{b}_{ij}/\lambda\right) d\Omega. \quad (1)$$

Imaging the output of a radio interferometer therefore consists of estimating  $I_\nu(\hat{r})$  given the available measurements  $V_{ij}^{ij}$ .

Naively one might attempt to solve equation 1 by discretizing, and subsequently solving the resulting matrix equation. If the interferometer is composed of  $N_{\text{base}}$  baselines, and measures  $N_{\text{freq}}$  frequency channels over  $N_{\text{time}}$  integrations then the entire data set consists of  $N_{\text{base}} N_{\text{freq}} N_{\text{time}}$  complex numbers. If the sky is discretized into  $N_{\text{pix}}$  pixels then the relevant matrix has

**Figure 2.** Dirty snapshot images after smearing the visibilities over the entire 100 hour observation window. The two bright source tracks correspond to Cas A (top track) and Cyg A (bottom track) smeared along a ring of constant declination. The sources dotting the horizon are faulty power line insulators.

dimensions of  $(N_{\text{base}}N_{\text{freq}}N_{\text{time}}) \times (N_{\text{pix}})$ . For making single-channel maps with the Owens Valley LWA this becomes a 5 petabyte array (assuming each matrix element is a 64-bit complex floating point number). This matrix equation is therefore prohibitively large, and solving equation 1 by means of discretization is usually impossible **TODO: cite Jayce's paper (has he published that yet?) where he does this, but explain why his work is the exception instead of the rule.**

Instead it is common to make mild assumptions that simplify equation 1 and ease the computational burden in solving for  $I_{\nu}(\hat{r})$ . For example, when all of the baselines  $\vec{b}_{ij}$  lie in a plane and the field-of-view is small, equation 1 can be well-approximated by a two-dimensional Fourier transform.

**TODO: discuss w-projection**

**TODO: discuss a-projection**

Zheng et al. (2017b)

### 3.1. *m*-Mode Analysis

On the other hand, transit telescopes can take advantage of a symmetry in equation 1 that greatly reduces the amount of computer time required to image the full-sky with exact incorporation of widefield imaging effects. This technique, called *m*-mode analysis, also obviates the need for gridding, mosaicing, and multi-scale deconvolution. Instead the entire sky is imaged in one coherent synthesis imaging step.

In this context we will define a transit telescope as any interferometer where the response pattern of the individual elements does not change with respect to time. This may be an interferometer like the OVRO LWA where

the correlation elements are fixed dipoles, but it may also be an interferometer like the MWA if the steerable beams are held in a fixed position (not necessarily at zenith).

We will briefly summarize *m*-mode analysis below, but the interested reader should consult Shaw et al. (2014, 2015) for a complete derivation.

For a transit telescope, the visibilities  $V_{\nu}^{ij}$  are a periodic function of sidereal time<sup>2</sup>. Therefore it is a very natural operation to compute the Fourier transform of the visibilities with respect to sidereal time  $\phi \in (0, 2\pi]$ .

$$V_{m,\nu}^{ij} = \int_0^{2\pi} V_{\nu}^{ij}(\phi) \exp(-im\phi) d\phi \quad (2)$$

The output of this Fourier transform is the set of *m*-modes  $V_{m,\nu}^{ij}$  where  $m = 0, \pm 1, \pm 2, \dots$  is the Fourier conjugate variable to the sidereal time. The *m*-mode corresponding to  $m = 0$  is a simple average of the visibilities over sidereal time. Similarly  $m = 1$  corresponds to the component of the visibilities that varies over half-day timescales. Larger values of *m* correspond to components that vary on quicker timescales.

**TODO: introduce the baseline transfer function because I will want to use it in later sections**

It can be shown that there is a discrete linear relationship between the *m*-modes  $V_{m,\nu}^{ij}$  and the spherical

<sup>2</sup> This is not strictly true. Ionospheric fluctuations and non-sidereal sources (such as the sun) will violate this assumption. This paper will, however, demonstrate that the impact on the final maps is mild.

harmonic coefficients of the sky brightness  $a_{lm,\nu}$ .

$$V_{m,\nu}^{ij} = \sum_l B_{lm,\nu}^{ij} a_{lm,\nu}, \quad (3)$$

where the transfer coefficients  $B_{lm,\nu}^{ij}$  define the interferometer's response to the sky. For example, the transfer coefficients are a function of the baseline and antenna primary beam pattern.

Equation 3 can be recognized as a matrix equation where the transfer matrix  $\mathbf{B}$  is block-diagonal.

$$\mathbf{B} = \begin{pmatrix} m=0 & & & \\ & m=\pm 1 & & \\ & & m=\pm 2 & \\ & & & \ddots \end{pmatrix} \quad (4)$$

The vector  $\mathbf{v}$  contains the list of  $m$ -modes and the vector  $\mathbf{a}$  contains the list of spherical harmonic coefficients representing the sky brightness. In order to take advantage of the block-diagonal structure in  $\mathbf{B}$ ,  $\mathbf{v}$  and  $\mathbf{a}$  must be sorted by the value of  $m$ .

$$\overbrace{\begin{pmatrix} v \\ \vdots \\ m\text{-modes} \\ \vdots \end{pmatrix}} = \overbrace{\begin{pmatrix} \ddots & & \\ & \text{transfer matrix} & \\ & & \ddots \end{pmatrix}}^{\mathbf{B}} \overbrace{\begin{pmatrix} a \\ \vdots \\ a_{lm} \\ \vdots \end{pmatrix}}^{\mathbf{a}} \quad (5)$$

In practice we now need to pick the set of spherical harmonics we will use to represent the sky. For an interferometer like the OVRO LWA with lots of short baselines, a sensible choice is to use all spherical harmonics with  $l \leq l_{\max}$  for some  $l_{\max}$ . The parameter  $l_{\max}$  is determined by the maximum baseline length of the interferometer. For an interferometer without short spacings, a minimum value for  $l$  might also be used. This  $l_{\min}$  parameter should be determined by the minimum baseline length. When creating the maps presented in this paper, we use  $l_{\min} = 0$  and  $l_{\max} = 1000$ .

The interferometer's sensitivity to  $l = 0$ , however, deserves special consideration. Venumadhav et al. (2016) prove – under fairly general assumptions – that an interferometer is only sensitive to the monopole of the sky brightness if there exists some form of cross-talk or common-mode noise pick-up. In fact, the sensitivity of the interferometer is proportional to the amplitude of these effects. For consistency we will include  $a_{00}$  while solving Equation 5 for the vector  $\mathbf{a}$ , but we set  $a_{00} = 0$  afterwards because we do not have a measurement of cross-talk or common-mode noise pick-up.

The size of a typical block in the transfer matrix is  $(2N_{\text{base}}N_{\text{freq}}) \times (l_{\max})$ . If each element of the matrix is stored as a 64-bit complex floating point number, a sin-

gle block is 500 MB for the case of single-channel imaging with the OVRO LWA. Compare this number with the 5 PB required for the naive approach. The power of  $m$ -mode analysis is the block-diagonal structure of equation 5. By breaking up the problem into  $N$  independent blocks, the computational complexity involved in inverting the equation is reduced by a factor  $N^3$ . For the case of the OVRO LWA the equation breaks up into  $\sim 10^3$  blocks and so we save a factor of  $\sim 10^9$  in processing time by using  $m$ -mode analysis.

Imaging in  $m$ -mode analysis essentially amounts to inverting equation 5 to solve for the spherical harmonic coefficients  $\mathbf{a}$ . The linear-least squares solution, which minimizes  $\|\mathbf{v} - \mathbf{B}\mathbf{a}\|^2$ , is given by

$$\hat{\mathbf{a}}_{\text{LLS}} = (\mathbf{B}^* \mathbf{B})^{-1} \mathbf{B}^* \mathbf{v}, \quad (6)$$

where  $*$  indicates the conjugate-transpose. However, usually one will find that  $\mathbf{B}$  is not full-rank and hence  $\mathbf{B}^* \mathbf{B}$  is not an invertible matrix. For example, an interferometer located in the northern hemisphere will never see a region of the southern sky centered on the southern celestial pole. The  $m$ -modes contained in the vector  $\mathbf{v}$  must contain no information about the sky around the southern celestial pole, and therefore the act of multiplying by  $\mathbf{B}$  must destroy some information about the sky. The consequence of this fact is that  $\mathbf{B}^* \mathbf{B}$  must have at least one zero eigenvalue, which means it is not invertible.

Another way of looking at the problem is that because the interferometer is not sensitive to part of the southern hemisphere, there are infinitely many possible solutions to equation 5 that will fit the measured data equally well. So we need to regularize the problem and apply an additional constraint that prefers a unique solution. For example, you may prefer that in the absence of any information the sky should be set to zero or you may prefer that the sky should be set to some prior expectation.

The process of Tikhonov regularization minimizes  $\|\mathbf{v} - \mathbf{B}\mathbf{a}\|^2 + \epsilon \|\mathbf{a}\|^2$  for some arbitrary value of  $\epsilon > 0$  chosen by the observer. The solution that minimizes this expression is given by

$$\hat{\mathbf{a}}_{\text{Tikhonov}} = (\mathbf{B}^* \mathbf{B} + \epsilon \mathbf{I})^{-1} \mathbf{B}^* \mathbf{v}. \quad (7)$$

Tikhonov regularization adds a small value  $\epsilon$  to the diagonal of  $\mathbf{B}^* \mathbf{B}$ , fixing the matrix's singularity. We can see this by using the singular value decomposition (SVD) of the matrix  $\mathbf{B} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ . Equation 7 becomes

$$\hat{\mathbf{a}}_{\text{Tikhonov}} = \mathbf{V}(\mathbf{\Sigma}^2 + \epsilon \mathbf{I})^{-1} \mathbf{\Sigma} \mathbf{U}^* \mathbf{v}.$$

The diagonal elements of  $\mathbf{\Sigma}$  are the singular values of  $\mathbf{B}$  and so the contribution of each singular component to the Tikhonov-regularized solution is scaled by  $\sigma/(\sigma^2 + \epsilon)$ , where  $\sigma$  is the singular value for the given singular

component. Tikhonov regularization therefore acts to suppress any component for which  $\sigma \lesssim \sqrt{\epsilon}$ . If  $\sigma = 0$ , the component is set to zero.

In practice the measurement  $\mathbf{v}$  is corrupted by noise with covariance  $\mathbf{N}$ . For illustrative purposes we now assume that  $\mathbf{N} = n\mathbf{I}$  for some scalar  $n$ . In this case the covariance of the Tikhonov-regularized spherical harmonic coefficients  $\mathbf{C} = \langle \hat{\mathbf{a}}_{\text{Tikhonov}}^* \hat{\mathbf{a}}_{\text{Tikhonov}} \rangle - \langle \hat{\mathbf{a}}_{\text{Tikhonov}} \rangle \langle \hat{\mathbf{a}}_{\text{Tikhonov}}^* \rangle$  is

$$\mathbf{C} = n\mathbf{V}\Sigma^2(\Sigma^2 + \epsilon\mathbf{I})^{-2}\mathbf{V}^*. \quad (8)$$

Each singular component is scaled by a factor of  $\sigma^2/(\sigma^2 + \epsilon)^2$ . In the absence of Tikhonov regularization ( $\epsilon = 0$ ) singular components with the smallest singular values – the ones that the interferometer is the least sensitive to – actually come to dominate the covariance of the measured spherical harmonic coefficients. Tikhonov regularization improves this situation by downweighting these components.

**TODO: describe the Moore-Penrose pseudoinverse and why I have elected not to use it**

While Tikhonov regularization will force unmeasured modes to zero, if a prior map of the sky already exists, it will be preferable to instead minimize  $\|\mathbf{v} - \mathbf{B}\mathbf{a}\|^2 + \epsilon\|\mathbf{a} - \mathbf{a}_{\text{prior}}\|^2$ .

Tikhonov regularization requires the observer to pick the value of  $\epsilon$ . If  $\epsilon$  is too large then too much importance is placed on minimizing the norm of the solution and the least-squares residuals will suffer. However if  $\epsilon$  is too small then the problem will be poorly regularized and the resulting sky map may not represent the true sky.

A tool that can be used to address this problem is the L-Curve.

### 3.2. *m*-Mode Analysis with the OVRO LWA

#### 3.3. CLEAN

#### 4. ERRORS

##### 4.1. Stationary Correlated Noise

However it is instructive to analyze the contaminating effect the RFI will have on *m*-mode analysis maps of the sky. The correlation observed on a given baseline and frequency channel for a single source of RFI is

$$V(t) = I(t)B^{\text{near-field}} \quad (9)$$

However we need a strategy to mitigate the RFI before imaging. A constant source attached to the horizon has a fringe rate of zero. The only possible astronomical origins for a source with zero fringe rate are:

1. a point source located at the north or south celestial poles, and
2. a ring of constant declination.

Therefore while snapshot images will show the RFI source on the horizon, extended integrations will show the RFI as rings of constant declination. We can take advantage of this discrepancy to separate astronomical emission from terrestrial RFI.

##### 4.2. Ionospheric Scintillation

One of the key assumptions made by *m*-mode analysis is that the sky is completely static. We assume that the only time-dependent behavior is the rotation of the Earth, which slowly rotates the sky through the fringe patterns of the interferometer. At low frequencies the ionosphere violates this assumption. In particular, ionospheric scintillation will cause even static sources to exhibit significant variability.

The correlation observed on a given baseline for a single point source is

$$V_\nu(t_{\text{sidereal}}) = I_\nu B_\nu(t_{\text{sidereal}}), \quad (10)$$

where  $I_\nu$  is the flux of the source at the frequency  $\nu$ , and  $B_\nu$  is the baseline transfer function. The transfer function is a function of the direction to the source, which is in turn a function of the sidereal time  $t_{\text{sidereal}}$ . If the source is varying, from intrinsic variability or due to scintillation, then the source flux is also a function of the time coordinate  $t$  such that

$$V_\nu(t_{\text{sidereal}}) = I_\nu(t)B_\nu(t_{\text{sidereal}}), \quad (11)$$

where  $t_{\text{sidereal}} = (t \bmod 23.9345 \text{ hours})$ .

Now assume we have observed with our interferometer for a single sidereal day. In order to compute the *m*-modes we must Fourier transform with respect to sidereal time. In a real measurement this is a discrete Fourier transform of the observed correlation with respect to time (where the sum over time is restricted to a sidereal day). **TODO: fix normalization**

$$V_{\nu,m} = \sum_t V_\nu(t)e^{-imt} \quad (12)$$

Define  $V_{\nu,m}^{\text{static}}$  to be the observed *m*-modes if the source was actually static ( $I_\nu(t) \equiv I_{\nu,0}$ ). Then as a consequence of the Fourier convolution theorem

$$V_{\nu,m} = \sum_{m'} V_{m'}^{\text{static}} I_{\nu,m-m'}. \quad (13)$$

This will tend to scatter power between *m*-modes. Simulate images of point sources with this
